ABSTRACT

We examine how bank efficiency during normal times affects survival, risk, and profitability during subsequent financial crises using data from five U.S. financial crises and preceding normal times. We find that cost efficiency during normal times helps reduce bank failure probabilities, decrease risk, and enhance profitability during subsequent financial crises, while profit efficiency has limited benefits. Results suggest that cost efficiency better measures management quality, while profit efficiency may partially reflect temporary high returns from risky investments during normal times. Findings have policy implications and imply that improving bank cost efficiency during normal times may promote better financial crisis performance.

1. Introduction

Financial crises are very costly for the real economy.¹ Much of the costs come from the banking industry. Bank failures and performance problems often result in significant negative externalities for other connected financial institutions, borrowers, creditors, and other parties in the real economy that depend on credit and other services from the failed and distressed institutions, as well as governments that frequently get involved in costly bailouts of these banks (e.g., Barth et al., 1990; James, 1991; Lang and Stulz, 1992; Ashcraft, 2005; Reinhart and Rogoff, 2009; Acharya et al., 2011; Laeven and Valencia, 2012; Kupiec and Ramirez, 2013; Kang et al., 2014). Thus, it is critical to understand the major determinants of bank performance during financial crises to tailor public policies, regulations, and management practices to detect and reduce the occurrence of bank problems early.

¹ To illustrate, the subprime financial crisis of the late 2000s is estimated to have cost the U.S. economy in the range of \$12 trillion–\$22 trillion, although many of the economic costs remain difficult to determine (U.S. Department of the Treasury, 2012; Atkinson et al., 2013; Government Accountability Office, 2013; Garcia, 2015).

As noted in one of the quotes above, bank problems during crises are frequently the result of bad decisions made during the normal times that precede them (Greenspan, 2001). One important reason may be institutional memory loss. When bank problems have not been prevalent for some time, bank loan officers and managers may suffer atrophy in their abilities to recognize and deal with such problems (e.g., Berger and Udell, 2004). It is therefore logical to look at normal times that precede financial crises to discover the determinants of bank performance during these crises. The extant literature on the determinants of bank performance generally focuses on the time periods immediately prior to this performance, irrespective of whether these are crises or normal times. This paper extends the literature by focusing on efficiency during the normal time periods preceding financial crises as determinants of crisis-times performance. This is important because crisis performance difficulties were most likely originated in the preceding normal times.

The literature on bank performance during crises is also generally limited in the factors that are examined. The focus is usually on accounting variables such as capital, liquidity, profitability, and loan quality (e.g., Lane et al., 1986; Espahbodi, 1991; Cole and Gunther, 1995, 1998; Helwege, 1996; Wheelock and Wilson, 1995, 2000; Calomiris and Mason, 1997, 2003; Molina, 2002; Elsinger et al., 2006; Schaeck, 2008; Admati et al., 2011; Cole and White, 2012; Knaup and Wagner, 2012; Berger and Bouwman, 2013; Hong et al., 2014; Berger et al., 2016), the scope of bank activities (investment banking, private equity, new financial products (e.g., Cole and White, 2012; DeYoung and Torna, 2013), bank ownership and corporate governance (e.g., Giannetti and Ongena, 2009; Fahlenbrach and Stulz, 2011; Berger and Bouwman, 2013; Berger et al., 2016; Calomiris and Carlson, 2017), and regional economic conditions (e.g., Aubuchon and Wheelock, 2010).

An overlooked factor affecting bank performance during crises is bank efficiency in the normal times prior to the crises. Researchers often study the effects of bank efficiency on bank performance (e.g., Cebenoyan et al., 1993; Hermalin and Wallace, 1994; Berger and Mester, 1997; Fiordelisi et al., 2011; Hughes and Mester, 2015), but none examine the effects of efficiency during normal times on performance during subsequent crises.

The closest paper in approach to ours is Berger and Bouwman (2013), who focus on the effects of capital during eight quarters of normal times prior to financial crises on bank survival and market share outcomes during the subsequent crises. Our contribution is quite different from theirs in that we focus on cost and profit efficiency as potential determinants of bank outcomes, controlling for bank capital and other factors included in the literature. In addition, while Berger and Bouwman (2013) include pre-crisis profitability as a control variable, we focus on profit efficiency as well as cost efficiency. Profit efficiency nets out the effects of product mix, variable input prices, fixed inputs and outputs, environmental factors, and random error.

We evaluate the effects of both normal-times cost and profit efficiency on bank performance because cost and profit efficiency measure different concepts and may affect future outcomes through different channels. Cost efficiency measures the proximity of a bank's cost to that of a best-practice or most efficient bank producing the same output that faced the same input prices and environmental conditions. Profit efficiency is the more general concept that includes revenues as well as costs. Profit efficiency measures the proximity of bank profits to those of a best-practice or most efficient bank under the same conditions. The "alternative profit efficiency" measure we employ is based on how much a bank earns relative to what would be earned by a best-practice bank that produced the same output and faced the same input prices and environmental conditions. Our findings for the two

types of efficiency are very different, justifying our separate treatment.

At first blush, cost and profit efficiency may seem to unconditionally lead to better future bank outcomes, but the reality is more complex. In fact, relatively high cost and profit efficiency during normal times can result in either favorable or unfavorable performance during subsequent financial crises. High cost efficiency in normal times may reflect superior managerial quality that endures through the following crisis and produces favorable performance. Alternatively, high cost efficiency during normal times may reflect "skimping" on resources to screen and monitor loan applicants, which saves resources during normal times, but creates poor loan outcomes that become apparent only during subsequent financial crises (e.g., Berger and DeYoung, 1997). Both of these channels may also apply to profit efficiency, which encompasses costs as well as revenues.

Additional channels may apply to profit efficiency. High profit efficiency may be associated with high charter values that result in favorable performance during subsequent financial crises because banks act to preserve these charter values. Alternatively, high profit efficiency during normal times may reflect excessive risk taking that earns high returns in normal times, but creates problems in subsequent crises.

Based on these channels, we formulate and test hypotheses for the effects of both cost and profit efficiency during normal times on bank failure, risk, and profitability during subsequent financial crises. The data include virtually all U.S. banks from five financial crises originally classified by Berger and Bouwman (2013), and their pre-crisis normal time periods – a total of 15,993 banks over the interval from 1986:Q1 to 2009:Q4. We include multiple financial crises and normal time periods to draw general conclusions and minimize the impact of idiosyncratic circumstances of a single crisis. The grouping of crises in the analysis is also helpful because it is never known in advance what type of crisis may be coming next, so our results can help bank stakeholders prepare for a multiplicity of eventualities.

We find that cost efficiency during normal times reduces failure probabilities, decreases risk, and enhances profitability during subsequent financial crises, while profit efficiency has limited benefits. These findings suggest that cost efficiency may proxy well for management quality, while profit efficiency may partially reflect temporary high returns during normal times from risky investments. Our results suggest that bank stakeholders – including policymakers, regulators, supervisors, owners, creditors, and managers – may consider monitoring more closely banks with low cost efficiency during normal times so as to reduce the occurrence of costly bank problems during financial crises. In addition, managerial policies and procedures that promote cost efficiency, could improve performance during subsequent crises. Our findings also suggest that researchers consider putting more trust in cost efficiency as an indicator of bank quality than profit efficiency.

We perform a variety of robustness checks. First, we test the sensitivity of our results to using alternative measures of bank performance. Second, we run the regressions separately for banking and market crises, those that originated in the banking sector and in financial markets, respectively. Third, we exclude banks that may be too-big-to-fail (TBTF) to mitigate the potential concern that our results may be driven by such banks. Fourth, we run tests when controlling for a simpler measure of efficiency used in the literature, total bank costs to total bank revenues (cost-to-income). Fifth, we consider alternative pre-crisis periods, measuring efficiency and control variables over the four quarters before a crisis instead of the full pre-crisis time period. Sixth, we consider the effects of efficiency on small versus large banks. Finally, we run tests which allow for the possibility of nonlinear relations between efficiency

and the bank performance. Our main findings stand up to all of these robustness checks.

The remainder of the paper is organized as follows. Section 2 discusses the cost and profit efficiency concepts and measurement. Section 3 describes the channels through which normal-times bank cost and profit efficiency may influence subsequent financial crisis performance and develops opposing hypotheses from these channels. Section 4 discusses our empirical framework – it gives our approach, describes the financial crises and normal times, and explains the regression models and key bank performance variables. Section 5 displays the data sample and sources. Section 6 reports reviews the summary statistics and presents our main regression results. Section 7 discusses robustness checks and Section 8 provides a deeper analysis of our cost efficiency results. Section 9 concludes.

2. Cost and profit efficiency concepts and measurement

2.1. Cost and profit efficiency concepts

Banks often pursue the economic goals of cost minimization and/or profit maximization. Researchers for the last three decades measure how well banks achieve these goals through the concepts of cost efficiency and profit efficiency. The cost efficiency of a bank tells us how close a bank's cost is to what a best-practice bank's cost for producing the same current level of output under the same conditions. It is measured by the ratio of the minimum cost a best-practice bank would incur to the bank's actual cost if the two banks produced the same output quantities and faced the same conditions (same input prices and environmental conditions).

Conversely, the profit efficiency of the bank tells us how close a bank is to producing the maximum possible profit of a best-practice banks under the same conditions. It is measured as the ratio of a bank's actual profit earned to the maximum profit a best-practice bank would attain for the same input prices, environmental conditions, and either output prices or quantities (e.g., Mullineaux, 1978; Berger et al., 1993; Soteriou and Zenios, 1999; Maudos et al., 2002). Profit efficiency is a broader concept than cost efficiency because the profit function allows for consideration of revenues as well as costs.

For our purposes in this paper, we take output quantities, rather than output prices as given, and measure "alternative profit efficiency." As discussed in Berger and Mester (1997), alternative profit efficiency is preferred as it provides additional information when some of the assumptions required by standard profit efficiency – relatively homogeneous output quality, easily-changed output quantities, highly competitive output markets, and well-measured output prices – do not hold. Because of the inherent benefits, most bank profit efficiency papers over the past 20 years use alternative profit efficiency (e.g., Vander Venet, 2002; Restrepo-Tobon and Kumbhakar, 2014; Wheelock and Wilson, 2016).

It might be expected that bank managers would always strive for both high cost and profit efficiency, that the two measures would be strongly positively correlated, and that both would predict favorable future outcomes, but the reality is more complex. Cost and profit efficiency may not be strongly positively related because bank outputs have quality differences that are difficult to measure. Higher-quality services may require higher costs and result in lower measured cost efficiency, but fetch higher output prices that result in higher profits and measured profit efficiency (e.g., Berger and Mester, 1997; Lozano-Vivas, 1997; Rogers, 1998; Maudos et al., 2002). Bank outputs may also have different risk characteristics that are challenging to measure. Higher-risk outputs typically have higher expected returns, which may boost profit efficiency during normal times and may not have favorable effects on cost efficiency. As discussed in Section 3, high cost and profit

efficiency during normal times may predict either favorable or unfavorable bank performance during subsequent financial crises, depending on the relative importance of several different channels.

2.2. Efficiency measurement

We measure both cost and profit efficiency for every bank for every quarter of the normal times periods, and use statistics computed over all the quarters of these periods to reduce the impact of outliers.

2.2.1. Variables included in the cost and alternative profit functions

The first step in computing efficiency is the choice of variables specified in the cost and alternative profit functions. We define total costs as total interest expenses plus total noninterest expenses, and total profits as total bank net income. We specify four input prices: w_1 , price of labor (ratio of total personnel expenses to number of employees); w_2 , price of physical capital (total operating and administrative expenses to total premises and fixed assets); w_3 , price of purchased funds ((total interest expenses - total interest on core deposits)/(quantity of total liabilities - core deposits)); and w_4 , price of core deposits ((total interest on deposits - interest on time deposits over \$100,000)/quantity of core deposits).² We use the following five output quantities: y_1 , consumer loans; y_2 , commercial and industrial (C&I) loans; y_3 , residential real estate (RRE) loans (1–4 family); y_4 , commercial real estate (CRE) loans (total real estate loans - RRE loans); y_5 , other loans (total loans - ($y_1 + y_2 + y_3 + y_4$)). We also include quantities of two fixed netputs (inputs or outputs): z_1 , the notional value of total bank off-balance sheet activities; and z_2 , bank financial equity capital.³ Finally, we include an environmental variable to account for the risk exposure of the bank, v , the weighted nonperforming loan ratio of all banks in the bank's state, where the weights are based on the proportions of deposits of the banks in the state.⁴

2.2.2. Specification of the cost and alternative profit functions

We use the Fourier-flexible functional form for the cost and alternative profit functions to estimate bank-specific efficiency measures, which are used subsequently in panel estimations of effects of bank efficiency on bank performance. Prior research shows that the Fourier-flexible form is preferable to functional forms based on second-order Taylor series expansions, such as the translog or normalized quadratic (e.g., Gallant, 1981, 1982; Berger and Mester, 1997). The Fourier-flexible form incorporates the translog and augments it by including Fourier trigonometric terms, so it is more

² Complete data for the input prices w_3 and w_4 are not available in the Call Report prior to 1997 due to insufficient information on the core deposits. Therefore, we calculate an average ratio of core deposits to total deposits for each bank over the periods that data are available. We assume that the bank uses the same ratio in the earlier time periods where we cannot determine this based on the Call Report (1986:Q1 – 1996:Q4). If for a bank we cannot compute the ratio described as no reports are available, we use the industry ratio average by size class.

³ In choosing outputs, we focus on modern banking theories in which banks intermediate deposits into loans and also engage in off-balance sheet activities. Under many of these theories, banks are special because they screen and monitor on-balance sheet loans and off-balance sheet loan commitments and similar claims to liquid funds (e.g., Diamond, 1984; Ramakrishnan and Thakor, 1984; Boyd and Prescott, 1986; James, 1987). We specifically exclude other earning assets or securities as outputs, since these are methods of storing liquidity for banks so that they might have funds available to make future loans or respond to liquidity shocks from liabilities or off-balance sheet activities. Under other recent theories of bank liquidity creation, securities actually subtract from banking output, and they receive negative weights in liquidity creation empirical measures (e.g., Bryant, 1980; Diamond and Dybvig, 1983; Berger and Bouwman, 2009). Thus, under these theories, securities are better thought of as inputs to the banking functions rather than outputs.

⁴ A small minority of banks are in multiple states. Since we only know the location of deposits from the Summary of Deposits data for these banks, we allocate nonperforming loans proportionately to the states according to the location of their deposits.

flexible than the translog, and is a global approximation to virtually any cost or profit function. In addition, many researchers found that it fits the data for U.S. banks better than other functional forms (e.g., McAllister and McManus, 1993; Mitchell and Onvural, 1996). For the cost function, we specify:

$$\begin{aligned}
 \ln(C/(w_4 z_2)) = & \delta + \sum_{i=1}^3 \beta_i \ln(w_i/w_4) \\
 & + \frac{1}{2} \sum_{i=1}^3 \sum_{j=1}^3 \beta_{ij} \ln(w_i/w_4) \ln(w_j/w_4) + \sum_{k=1}^5 \gamma_k \ln(y_k/z_2) \\
 & + \frac{1}{2} \sum_{k=1}^5 \sum_{m=1}^5 \gamma_{km} \ln(y_k/z_2) \ln(y_m/z_2) + \delta_1 \ln(z_1/z_2) \\
 & + \frac{1}{2} \delta_{11} \ln(z_1/z_2) \ln(z_1/z_2) \\
 & + \sum_{i=1}^3 \sum_{k=1}^5 \eta_{ik} \ln(w_i/w_4) \ln(y_k/z_2) + \sum_{i=1}^3 \rho_i \ln(w_i/w_4) \ln(z_1/z_2) \\
 & + \sum_{k=1}^5 \tau_k \ln(y_k/z_2) \ln(z_1/z_2) + \sum_{n=1}^9 [\phi_n \cos(x_n) + \omega_n \sin(x_n)] \\
 & + \sum_{n=1}^9 \sum_{q=n}^9 [\phi_{nq} \cos(x_n + x_q) + \omega_{nq} \sin(x_n + x_q)] \\
 & + \sum_{n,n',n''=1}^9 [\phi_{nn'n''} \cos(x_n + x_{n'} + x_{n''}) + \omega_{nnn} \sin(x_n + x_{n'} + x_{n''})] \\
 & + \zeta_1 \ln v + \ln u_c + \ln \varepsilon_c \quad (1)
 \end{aligned}$$

where (y_k/z_2) and (z_1/z_2) have one added to avoid taking the natural log of zero, the x_n 's are rescaled terms of the $\ln(w_i/w_4)$, $\ln(y_k/z_2)$, and $\ln(z_1/z_2)$, so that each of the x_n lies in the interval $[0, 2\pi]$, where π indicates radians (rather than profits as below).⁵ We apply the standard symmetry restrictions to the translog part of the function (i.e., $\beta_{ij} = \beta_{ji}$, $\gamma_{km} = \gamma_{mk}$). In the composed error term, $\ln \varepsilon_c$ represents noise and $\ln u_c$ represents cost inefficiency.

The alternative profit function requires a few changes. The dependent variable is $\ln[(\pi/w_4 z_2) + |(\pi/w_4 z_2)^{\min}| + 1]$, where $|(\pi/w_4 z_2)^{\min}|$ indicates that the absolute value of the minimum value of normalized profit, and the $|(\pi/w_4 z_2)^{\min}| + 1$ is added so we can take the natural log of a positive number, since minimum profits are usually negative. The composed error is $\ln u_\pi + \ln \varepsilon_\pi$.

As shown above, we normalize the cost, profit, and input price terms by the last input price w_4 to ensure linear homogeneity, and normalize cost, profit, output quantities, and fixed netput quantities by the last fixed netput financial equity capital z_2 . These normalizations are fairly standard in the cost and profit function literature. Normalizing by one input price in the Fourier-flexible functional form is the only way to ensure linear homogeneity, so that doubling all input prices exactly doubles costs on the efficient frontier. Normalization by a fixed netput makes sure that the banks are treated comparably and not subject to scale bias – otherwise the large banks would dominate the regressions. Normalization by equity helps with economic interpretation of the profit function, given that the dependent variable is proportional to profits per dollar of equity, or return on equity.

2.2.3. Measuring efficiency from the estimated cost and alternative profit functions

The key to measuring efficiency is disentangling inefficiency $\ln u$, from random error $\ln \varepsilon$. Since we have a number of time periods, our preferred method for the estimation of efficiency is the distribution-free approach, which disentangles them by assuming that inefficiencies are relatively stable and random errors tend to average out to zero over time (Berger, 1993).

We estimate the cost and alternative profit functions separately for each quarter of a normal-times interval to account for possible changes over time in technology, regulation, and external environment. We then average the residuals over all the quarters of the normal-times period to obtain preliminary estimates of the inefficiency term $\ln u$ for each bank, effectively assuming that the random error $\ln \varepsilon$ averages out to zero over time. To avoid the impact of extreme values, we follow Berger and Mester (1997) and winsorize the extreme values. Specifically, those banks in the top and bottom 5% are assigned values of banks at the 95th and 5th percentiles, respectively.⁶ Cost efficiency for each bank and each quarter is estimated as the ratio of minimum predicted cost for that bank to the actual predicted costs. The minimum predicted cost for the bank uses the values of the cost function arguments for that bank and the minimum cost function truncated average residual for the sample. The actual predicted costs for the bank also use the values of the cost function for that bank combined with the truncated average residual for the bank.

These cost efficiencies are then ranked for each quarter in descending order of efficiency, so that a bank that is more efficient than 80% of the observations for that quarter is assigned a 0.80 cost efficiency rank for that quarter. We then average the ranks over all the quarters of the normal-times period to obtain a comparable measure to use in our regression models of bank performance in the subsequent financial crisis. We prefer efficiency ranks to levels because ranks remove changes in the distributions of efficiency over time that are not relevant to our hypotheses. Average profit efficiency ranks are determined in similar fashion, except that they are based on the ratio of actual predicted profit for that bank to the maximum predicted profit.⁷

3. Hypothesis development

We next discuss channels through which normal-times bank cost and profit efficiency may affect likelihood of failure, risk, and profitability of banks during subsequent financial crises, and form hypotheses from these channels. Section 3.1 describes the cost efficiency channels, Section 3.2 explains the profit efficiency channels, and Section 3.3 gives the resulting hypotheses.

3.1. Channels for bank cost efficiency

High cost efficiency during normal times can have either favorable or unfavorable effects on bank performance during subsequent financial crises. The favorable effects go through the following channel:

- *Good management channel:* If management that is proficient at keeping costs down during normal times is also proficient at managing portfolios, then high cost efficiency may

⁵ Following Berger and Mester (1997), we cut 10% off each end of the $[0, 2\pi]$ interval so that the x_n span $[0.1 \times 2\pi, 0.9 \times 2\pi]$ to reduce approximation problems near the endpoints. The formula for x_n is $(0.2 \times \pi - \mu \times a + \mu \times \text{variable})$, where $[a, b]$ is the range of the variable being transformed and $\mu \equiv (0.9 \times 2\pi - 0.1 \times 2\pi)/(b - a)$.

⁶ Our results are robust when we alternatively winsorize at 2.5% and 97.5% levels and at 1% and 99% levels.

⁷ We do not include bank fixed effects in the cost and profit function estimations because these regressions are estimated quarterly and have only one bank observation per quarter. However, our efficiency estimation methods that are based on averaging the residuals may be thought of as similar to bank fixed effects.

be associated with lower likelihood of bank failure, lower risk, and greater profitability during subsequent financial crises (e.g., Berger and DeYoung, 1997; Kwan and Eisenbeis, 1997; Williams, 2004).

The unfavorable effects of high cost efficiency operate through the following alternative channel:

- *Skimming channel*: Banks may achieve high cost efficiency during normal times by devoting relatively few resources to screening and monitoring loan applicants. This “skimming” channel, introduced by Berger and DeYoung (1997), improves cost efficiency during normal times and may not be noticed because the resulting poor loan performance only becomes apparent during subsequent financial crises.

3.2. Channels for bank profit efficiency

Profit efficiency may operate through the same two channels as cost efficiency because profit efficiency includes the effects of costs as well as revenues. Thus, the *good management channel* may also apply to profit efficiency because good cost managers are not expected to be significantly worse at managing revenues. Similarly, the *skimming channel* may also apply to profit efficiency as long as revenues during normal times are not significantly adversely affected by skimming. This may occur because even poor loans may perform well outside of crisis periods.

There are two additional channels through which profit efficiency during normal times may favorably or unfavorably affect financial crisis performance. The additional favorable effects go through the following channel:

- *Charter value channel*: A bank with high profit efficiency may be expected to have relatively high future profits, and therefore greater charter value. It is often found that banks with greater charter value due to a different source, market power, behave more prudently to protect this value (e.g., Marcus 1984, Keeley 1990, Demsetz et al., 1996, Hellmann et al., 2000, Carletti and Hartmann 2003, Jimenez et al., 2013). The same logic applies to high profit efficiency, since banks with high profit efficiency are generally more profitable. Thus, banks with high normal-times profit efficiency may behave more prudently and be more likely to survive, have relatively low risk, and relatively high profits during subsequent financial crises.

The additional unfavorable effects go through the following channel:

- *Risk-taking channel*: Banks may achieve high profit efficiency during normal times by taking on more risk, since high-risk investments generally have higher returns during normal times. The higher risk-taking during normal times may turn into higher failure probabilities, higher risk, and lower profitability during subsequent crises, when high-risk investments generally suffer losses.⁸

3.3. Hypotheses derived from the channels

These channels imply two opposing hypotheses each for the effects of normal-times bank cost and profit efficiency on performance during subsequent financial crises:

Hypothesis 1a. Higher cost efficiency during normal times results in better performance (lower likelihood of failure, lower risk, and higher profitability) during subsequent financial crises.

Hypothesis 1b. Higher cost efficiency during normal times results in worse performance (higher likelihood of failure, higher risk, and lower profitability) during subsequent financial crises.

Hypothesis 2a. Higher profit efficiency during normal times results in better performance (lower likelihood of failure, lower risk, and higher profitability) during subsequent financial crises.

Hypothesis 2b. Higher profit efficiency during normal times results in worse performance (higher likelihood of failure, higher risk, and lower profitability) during subsequent financial crises.

These hypotheses may apply to different degrees to different sets of banks. Our empirical analysis tests which of Hypotheses 1a or 1b and which of 2a and 2b empirically dominates the other overall.

4. Empirical framework

This section explains our empirical approach for the failure, risk, and profitability analyses. It also describes the financial crises and normal times.

4.1. Empirical approach and descriptions of financial crises and normal times

Our main approach pools the data to treat financial crises and their preceding normal times as a group. We focus on five crises that occurred between 1986:Q1 and 2009:Q4, which were created by Berger and Bouwman (2013). They include two banking crises (crises that originated in the banking sector) and three market crises (originated outside banking in the financial markets). The banking crises are the credit crunch of the early 1990s (1990:Q1–1992:Q4) and the subprime lending crisis (2007:Q3–2009:Q4). The market crises are the 1987 stock market crash (1987:Q4); the Russian debt crisis and Long-Term Capital Management (LTCM) bailout of 1998 (1998:Q3–1998:Q4); and the bursting of the dot.com bubble and the September 11 terrorist attacks of the early 2000s (2000:Q2–2002:Q3). Normal times include all the quarters since previous crisis, except the first normal times period begins at the start of the data set. The financial crises and normal times are graphed in Fig. 1. As discussed above, in our main analysis, we include all the crises in order to draw general conclusions and because it is never known which type of crisis is coming next.

Thus, for the full sample, we have a five-period panel, in which each period corresponds to a different financial crisis. The dependent variables are measures of performance during the crises, and the explanatory variables are measured during the normal time period preceding these financial crises. We have an unbalanced panel, given that some banks enter the sample later, fail, or are merged out of existence during the sample, with the number of observations for each bank varying between one and five. All dependent and independent variables are averages of the quarterly values over the appropriate crisis or normal time period.

4.2. Regression models

We estimate the following model:

$$\text{Performance Indicator}_{i,t} = f(\text{COSTEFF}_{i,\text{PRE}-t}, \text{PROFITEFF}_{i,\text{PRE}-t}, \text{Other Bank Characteristics}_{i,\text{PRE}-t}, \text{Crisis}_{i,t}). \quad (2)$$

⁸ To illustrate, banks' investments in mortgage-backed securities (MBS) were very profitable during the normal time period prior to the subprime financial crisis, but proved very risky and a significant contributing factor to bank failures and the crisis (e.g., Acharya et al., 2009; Acharya and Richardson, 2009; Diamond and Rajan, 2009).

Detailed periods and sequence for our sample period from 1986:Q1 until 2009:Q4 are represented below:

Period Type	Exact time period
NORMAL	86:Q1 - 87:Q3
MKT_CRISIS	87:Q4

Fig. 1. Timeline This figure shows the banking crises (BNK_CRISIS), market crises (MKT_CRISIS), and normal times (NORMAL) that occurred during our sample period from 1986:Q1 until 2009:Q4.

Performance Indicator $_{i,t}$ is a measure of bank i 's failure, risk, or profitability during crisis period t , $t \in \{1,2,3,4,5\}$. Specifically, our performance measures are as follows. For failure, we use:

- (i) $FAILED1_{i,t}$, a dummy equal to one if bank i failed as it was placed under receivership or closed by the Federal Deposit Insurance Corporation (FDIC), given it was unable to meet its obligations to depositors and other stakeholders,⁹ and thus was included in the FDIC failure list, or experienced book-value insolvency or technical default (bank became critically undercapitalized, its equity capitalization fell below 2% of bank gross total assets (GTA)¹⁰)¹¹ in crisis period t .
- (ii) $FAILED2_{i,t}$, a dummy equal to one if bank i failed as it was placed under receivership or closed by the Federal Deposit Insurance Corporation (FDIC), given it was unable to meet its obligations to depositors and other stakeholders, and thus was included in the FDIC failure list in crisis period t .

We prefer $FAILED1$ as our main measure of bank failure, given it is more comprehensive, including bank technical defaults, consistent with other prior research in banking (e.g., [Wheelock and Wilson, 1995, 2000](#); [Cole and White, 2012](#)). $FAILED2$ is also used as an alternative.

As proxies for risk,¹² we use:

- (i) $LN(ZSCORE)_{i,t}$, log of the sum of a bank's mean ROA (net income over GTA) and mean CAPITAL RATIO (equity capital over GTA) divided by σROA (the volatility of ROA), where the means of the components are calculated over crisis period t .
- (ii) $\sigma ROA_{i,t}$, volatility of return on assets (ROA) of bank i over crisis period t .

As proxies for profitability, we use:

- (i) $ROA_{i,t}$, return on assets (net income over GTA) of bank i averaged over crisis period t .
- (ii) $ROE_{i,t}$, return on equity (net income over capital equity) of bank i averaged over crisis period t .¹³

Eq. (2) is run as a **logit** for the failure variables, and as OLS for the continuous outcome measures. $COSTEFF_{i,PRE-t}$, and $PROFITEFF_{i,PRE-t}$ are profit and cost efficiency ranks over the normal time period prior to the financial crisis. *Other Bank Characteristics* $_{i,PRE-t}$ is a set of control variables averaged over the normal times period. $Crisis_{i,t}$ is a set of individual crises dummies, which act as time fixed effects. We exclude one crisis dummy to avoid perfect collinearity.

To address potential concerns that error terms may be heteroscedastic or correlated across time periods for each bank, we run all regressions adjusting the standard errors for heteroscedasticity and within-bank clustering.

5. Data sample, sources, and control variables

This section first explains our data sample and sources, followed by details on the control variables. The key independent variables measuring efficiency are described in [Section 2](#) above. [Table 1](#) Panel A shows variable definitions.

bers of observations than the variables for failure and performance, dropping from 48,532 to 35,151 observations.

¹³ To address concerns related to differences in performance for banks with potentially different tax treatments (e.g., S corporations versus C corporations), we also try using alternative definitions of ROA and ROE that use income before applicable income taxes over GTA and equity capital, respectively. Untabulated results using these alternative definitions are consistent with our main findings.

⁹ As receiver, the FDIC has the role to resolve a failed institution in order to maximize the return on the assets of the failed bank and minimize any loss to the deposit insurance fund. To accomplish a resolution, FDIC can 1) merge a failed institution with another insured depository institution and transfer its assets and liabilities, 2) form a new institution, known as a bridge bank, to take over the assets and liabilities of the failed institution, or 3) sell or pledge the assets of the failed institution to the FDIC in its corporate capacity (e.g., [FDIC, 2013](#)). The FDIC bank failure list is available at: <https://www.fdic.gov/bank/individual/failed/banklist.html>.

¹⁰ As discussed in [Berger and Bouwman \(2013\)](#) and elsewhere, gross total assets (GTA) equals total assets plus the allowance for loan and lease losses and the allocated transfer risk reserve (a reserve for certain foreign loans). Total assets on Call Reports deduct these two reserves, which are held to cover potential credit losses. We add these reserves back to measure the full value of the assets financed.

¹¹ This definition of technical default is consistent with the FDIC Improvement Act of 1991, which requires regulators to close or impose prompt corrective actions on any bank whose equity ratio falls below 2% (critically undercapitalized).

¹² Both risk measures, $LN(ZSCORE)$ and σROA , cannot be calculated over one of the market crises – the stock market crash of 1987:Q4 – which lasts only one quarter. The statistics and regressions using these measures therefore have smaller num-

Table 1

Variable definitions and summary statistics.

Panel A provides definitions for all variables used in our analysis. Panel B reports summary statistics of the variables for our analysis for the period 1986:Q1–2009:Q4. All variables using dollar amounts are expressed in real 2009:Q4 dollars using the implicit GDP price deflator. It contains means, medians, standard deviations and number of observations on all the regression variables used to examine the effect of pre-crisis cost and profit efficiency on banks' ability to survive crises, reduce risk, and increase their performance during such crises. We first present statistics for all financial crises, and then we distinguish between banking crises (the credit crunch of the early 1990s and the recent subprime lending crisis), and market crises (the 1987 stock market crash, the Russian debt crisis plus LTCM bailout in 1998, and the bursting of the dot.com bubble plus September 11).

Panel A – Variable definitions

Dependent variables**FAILURE**

FAILED1 is a dummy equal to one if bank *i* failed as it was placed under receivership or closed by the FDIC given it was unable to meet its obligations to depositors and other stakeholders and thus it was included in the FDIC failure list, or experienced book-value insolvency or technical default (bank became critically undercapitalized, its equity capitalization fell below 2% of bank GTA).

FAILED2 is a dummy equal to one if bank *i* failed as it was placed under receivership or closed by the FDIC given it was unable to meet its obligations to depositors and other stakeholders and thus it was included in the FDIC failure list.

RISK

LN(ZSCORE) is a measure of bank financial risk. It is calculated as the log of the sum of a bank's mean *ROA* (net income over GTA) and mean *CAPITAL RATIO* (equity capital over GTA) divided by σROA (the volatility of *ROA*), where the means of the components are calculated over the crises periods.

σROA is the volatility of return on assets *ROA* over the crises periods.

PROFITABILITY

ROA is the bank return on assets over the crises periods.

ROE is the bank return on equity over the crises periods winsorized at the 1% level.

OTHER DEPENDENT VARIABLES (Robustness)

NPL/TL is the bank ratio of nonperforming loans (past due at least 90 days or in nonaccrual status) to total loans.

LLA/GTA is loan loss allowance divided by GTA.

Key independent variables

COSTEFF is bank cost efficiency over the pre-crisis periods.

PROFEFF is bank profit efficiency over the pre-crisis periods.

Basic characteristics

COST EFF MOMENTUM is the proportion of quarters in which the cost function residual ranks improved over the normal times period.

PROFIT EFF MOMENTUM is the proportion of quarters in which the profit function residual ranks improved over the normal times period.

Other bank characteristics**A. Risk and opacity**

CAPITAL RATIO is bank capitalization, defined as the bank's total equity divided by GTA.

TOTAL LOANS / GTA is the ratio of total loans to GTA.

COMMERCIAL RE RATIO is the commercial real estate loans divided by GTA.

BROKERED DEPOSITS RATIO is brokered deposits divided by GTA.

UNUSED COMMITMENTS RATIO is unused commitments divided by GTA.

CASH HOLDINGS RATIO is cash holdings divided by GTA.

LLA/GTA is loan loss allowance divided by GTA.

LOAN CONCENTRATION is a bank's loan portfolio concentration measured as a Herfindahl-Hirschman Index (HHI) of the following six loan categories: commercial real estate, residential real estate, construction and industrial, consumer, agriculture, and other loans.

B. Size and safety net protection

LN(GTA) is bank size calculated as the natural log of GTA.

SUPERVISOR_OCC is a dummy equal 1 if the OCC is the primary supervisor of the bank.

SUPERVISOR_FDIC is a dummy equal 1 if the FDIC is the primary supervisor of the bank.

SUPERVISOR_FRS is a dummy equal 1 if the FRS is the primary supervisor of the bank.

C. Bank ownership

BHC MEMBER is a dummy variable that equals one if a bank was part of a bank holding company (BHC) at any time in the pre-crisis period.

PUBLICLY LISTED is a dummy equal to 1 if a bank is listed or is part of a BHC that is listed on a stock exchange.

FOREIGN OWNERSHIP is a dummy equal to 1 if a bank has 50% or more foreign ownership.

D. Organizational structure

BRANCHES / GTA is a measure of bank organizational complexity calculated as (ratio of the number of branches the bank has active over GTA) $\times 1000$.

LN (NUMBER STATES) is the log of the number of states in which bank has branches.

E. Competition

HHI DEPOSITS is the bank-level Herfindahl-Hirschman Index (HHI) of deposit concentration for the local markets in which the bank is present.

PERCENT METROPOLITAN is the percentage of bank deposits in metropolitan markets (MSAs and CBSAs) as a fraction of deposits in all markets in which a bank is active.

F. Local economic conditions

CHANGE COINCIDENT INDEX is the weighted average of the changes in the Philadelphia Federal Reserve's state coincident indexes with the share of the deposits of a given bank taken as weights.

HOUSE PRICE INFLATION is the weighted average growth in a state-level house price index with the share of the deposits of a given bank taken as weights.

G. Other variables (Robustness)

CRISIS FIXED EFFECTS are a set of individual crisis dummies, which act as time fixed effects.

Enforcement Actions against Management is the number of regulatory enforcement actions against bank management by the corresponding banking regulator (Federal Reserve System (FRS), Federal Deposit Insurance Corporation (FDIC), and Office of the Comptroller of the Currency (OCC)) during the time period.

COST-TO-INCOME is the ratio of bank total costs to total revenue.

COST-TO-INCOME RANK is the rank of the ratio of bank total costs to total revenue in descending order of efficiency, so that banks with a lower ratio are assigned a higher rank.

5.1. Data sample and sources

We acquire bank data from quarterly Call Reports, which contain financial information on all U.S. commercial banks, over the period 1986:Q1 to 2009:Q4.¹⁴ We adjust the data to be in real 2009:Q4 terms using the GDP price deflator. We omit observations that do not refer to commercial banks, observations with missing or incomplete financial data on basic accounting variables such as total assets and equity, as well as those with no outstanding loans or deposits. Finally, following [Berger and Bouwman \(2013\)](#) and

others, for all observations with total equity less than 1% of total assets, we replace equity with 1% of total assets to minimize distortions in ratios that contain equity.¹⁵ Variables are aggregated for each bank over financial crises and normal time periods. These leaves us with a final sample of 48,532 bank-time period observations for 15,993 commercial banks over the sample period.¹⁶

¹⁵ For example, if a bank's capital to GTA ratio is less than 1%, we calculate ROE as net income divided by 1% of assets. Otherwise, for observations for which equity is between 0% and 1% of assets, dividing by equity would result in extraordinarily high values. When equity is negative, the conventionally-defined ROE would have a reversed sign and would not make economic sense. We do not drop these low or negative capital observations because they are likely the most informative of banks' ability to survive and thrive during financial crises. This same procedure is used in [Berger and Bouwman \(2013\)](#) and elsewhere.

¹⁶ In an unreported robustness test, we exclude bank-time period observations (5,466) that are affected by mergers as per the Federal Reserve Bank of Chicago

¹⁴ We focus on U.S. commercial banks, rather than BHCs, given that banks within holding companies have their own board of directors and managers, and thus many of the managerial decisions are made at the bank level. In addition, BHCs engage in many other activities that are more difficult to standardize than our simple banking outputs. However, we do control for whether banks are members of BHCs in all our models to capture any differences that may be driven by this membership.

5.2. Control variables

In our main performance regressions, we specify both a basic and a broad set of control variables. The basic set includes *COST EFF MOMENTUM* and *PROFIT EFF MOMENTUM*, the proportions of quarters in which the cost and profit function residual ranks, respectively, improved over the normal times period. It is expected that banks that improved their efficiencies more over a normal times period would have more momentum to perform better over the subsequent crisis period than banks that decreased efficiency. The basic controls also include *CRISIS FIXED EFFECTS*, the set of individual crises dummies, which act as time fixed effects.

In the broad set of controls, we also include proxies for risk and opacity, size and safety net protection, ownership, organizational structure and strategy, competition, and location, described below. In all cases, the control variables are measured during each pre-crisis normal-times period before the performance variables, which are measured during the subsequent crises.

5.2.1. Risk and opacity indicators

Banks with riskier and more opaque portfolios in the pre-crisis normal times may be more likely to fail, have higher risk, and less profitability during subsequent financial crises (e.g., Ng and Rusticus, 2011). Proxies for risk and opacity are as follows. *CAPITAL RATIO*: Bank capitalization is defined as the bank's equity divided by GTA. It measures the extent to which a bank can absorb potential losses and is generally thought to be associated with improved monitoring and reduced moral hazard incentives to take risk. This variable is found to reduce probability of failure in almost all bank failure studies (e.g., Cole and White, 2012) and to improve performance during financial crises (e.g., Berger and Bouwman, 2013). *TOTAL LOANS / GTA*: The ratio of total loans to GTA. Banks with higher loan ratios tend to have greater credit risk. *COMMERCIAL RE RATIO*: Commercial real estate loans divided by GTA. Research finds that commercial real estate loans is an important determinant of bank failures during the recent financial crisis (e.g., Cole and White, 2012; Berger et al., 2016). *BROKERED DEPOSITS RATIO*: Brokered deposits divided by GTA. Some banks obtain large deposits from deposit brokers. Such deposits however are expensive, and the funds are usually invested in high-risk activities to cover the high costs. While some researchers suggest that brokered deposits cannot directly explain bank failure (e.g., Rossi, 2010), others suggest otherwise (e.g., Federal Deposit Insurance Corporation, 2011; Cole and White, 2012). *UNUSED COMMITMENTS RATIO*: Unused commitments divided by GTA. As noted in Cornett et al. (2011), unused commitments expose banks to liquidity risk, and also experience an increase in demand during crises. *CASH HOLDINGS RATIO*: Cash holdings divided by GTA. High cash holding can reduce liquidity risk for banks and could help them survive, but they can also be associated with more agency problems (e.g., Jensen 1986). *LLA / GTA*: Loan loss allowance divided by GTA. The loan loss allowance measures expected future loan losses, and indicates greater credit risk.¹⁷ *LOAN CONCENTRATION*: A bank's loan portfolio concentration is measured as a Herfindahl-Hirschman Index (HHI) of the following six loan categories: commercial real estate, residential real estate, commercial and industrial, consumer, agriculture, and other loans. The larger is the loan HHI is, the more concentrated and potentially riskier is the loan portfolio.

5.2.2. Size and regulatory indicators

We control for size and safety net protection using several indicators. *LN(GTA)*: The natural log of GTA. Bank size is expected to have favorable effects on future performance because larger banks are better diversified, have higher survival odds, and scale economies (e.g., Berger and Mester, 1997; Wheelock and Wilson, 2012; Hughes and Mester, 2013). The largest banks may also have better safety net protection, which we deal with in a robustness check below. We control for the primary federal supervisor, which may affect bank performance during financial crises because of differences in quality of oversight and leniency: *SUPERVISOR_OCC* (for national banks), *SUPERVISOR_FDIC* (for state nonmember banks), and *SUPERVISOR_FRS* (for state banks that are members of the Federal Reserve System). We exclude the latter from the regressions to avoid perfect collinearity.

5.2.3. Bank ownership indicators

We use three indicators of bank ownership. *BHC MEMBER*: Dummy equal to one if the bank was part of a bank holding company (BHC) at any time in the period preceding the crisis. BHC membership is expected to help a bank survive, reduce its risk, improve its profitability during a crisis because the holding company may act as a source of strength to all the banks it owns (Houston et al., 1997). *PUBLICLY LISTED*: Dummy equal to 1 if a bank is listed or is part of the BHC that is publicly owned. Banks that are publicly listed have increased monitoring from shareholders and an additional source for raising capital, which may positively affect performance. Alternatively, it may increase failure probability and risk because of heightened incentives to take advantage of debt holders and the government safety net relative to private owners, which are often family members (e.g., Armour and Gordon, 2014; Cheng et al., 2015). *FOREIGN OWNERSHIP*: Foreign ownership dummy equal to 1 if a bank has 50% or more foreign ownership.

5.2.4. Organizational structure indicators

Centralized organizations are complex and tend to rely on hard information, while decentralized organizations are less complex and rely more on soft information (Stein, 2002), so organizational complexity may affect performance. We create two variables that capture this complexity: *BRANCHES / GTA*: (ratio of total bank branches over GTA) x 1000, and *LN (NUMBER STATES)*: Natural log of the number of states in which the bank has branches. Banks with more branches per dollar of assets and those that operate in more states tend to have more complex organizational structures.

5.2.5. Competition indicators

Some research suggests that increased competition reduces franchise value and increases risk and the likelihood of failure (e.g., Keeley, 1990). Others argue that competition reduces risk and the likelihood of failure (e.g., Boyd and De Nicolò, 2005). Still others suggest the relation may be nonmonotonic (e.g., Martinez-Miera and Repullo, 2010). The empirical research finds some merit in all of these positions (e.g., Beck et al., 2006, 2008, De Jonghe; Berger et al., 2016). We control for the degree of bank local competition, proxied by *HHI DEPOSITS*, measured using the Herfindahl-Hirschman Index (HHI) of market concentration based on the bank's weighted market share of deposits in the markets in which it operates. Markets are Metropolitan Statistical Areas (MSAs), New England County Metropolitan Areas (NECMAs), or rural counties.¹⁸ The larger is HHI, the greater is a bank's market power. Finally, we control for *PERCENT METROPOLITAN* – percentage of bank deposits

mergers dataset. All our results remain consistent and similar to our main findings using this treatment of the data. We keep these observations in for our main analysis as M&As are key ways in which banks may improve their performance.

¹⁷ We obtain qualitatively similar results when using the ratio of nonperforming loans to GTA instead of LLA/GTA as a proxy for bank asset quality.

¹⁸ HHI is the sum of the squares of the market shares (deposits) of each individual bank. We use the bank deposit data from the FDIC Summary of Deposits for the period 2005 to 2009 combined with data from Christa Bouwman for the period 1986 to 2004.

in metropolitan markets (MSAs and CBSAs). Banks with a higher metropolitan presence may experience more competition.

5.2.6. Local economic conditions indicators

We use two indicators of local economic conditions. *CHANGE COINCIDENT INDEX*: Weighted average of the changes in the Philadelphia Federal Reserve's state coincident indices based on deposit shares. The coincident index combines four state-level indicators to summarize economic conditions.¹⁹ Banks in states with better economic conditions may be less likely to fail, less risky, and more profitable (e.g., Bayazitova and Shivdasani, 2012). *HOUSE PRICE INFLATION*: House price index (HPI) growth is the weighted average growth in a state-level HPI from the Federal Housing Finance Agency (FHFA) based on deposit shares. This may have important effects on bank performance since real estate is often used as collateral.

6. Empirical analysis

6.1. Summary statistics

Table 1 Panel B contains summary statistics for all financial crises, and separately for banking and market crises. The dependent performance variables are measured during the crises and the independent efficiency and control variables are measured during the prior normal-times periods. The average bank has a failure (*FAILED1*) likelihood of 1.7% when considering actual FDIC bank failures and bank technical default (capitalization ratio of less than 2%), and a failure (*FAILED2*) likelihood of 0.8% when considering actual FDIC failures alone. The risk variables are *LN(ZSCORE)*, with a mean of 3.200 (mean of *ZSCORE* is 49.243), and standard deviation of *ROA*, σ *ROA*, with a mean of 0.008. Bank *ZSCORE*, which measures risk inversely, is considered to be the more complete measure of risk, since it takes into account capital and mean earnings, as well as the standard deviation of earnings. Profitability is measured by return on assets (*ROA*) with a mean of 0.005; and return on equity (*ROE*) with a mean of 0.059.

Our key independent variables measured during the pre-crisis normal times periods are *COSTEFF*, with a mean of 0.500, and *PROFITEFF*, with a mean of 0.498. The efficiency means are around 0.50 by construction of the ranks.

Turning to the controls, *COST EFF MOMENTUM* and *PROFIT EFF MOMENTUM* have means of 0.596 and 0.591, respectively. These means exceed the means of the efficiency rank distributions of 0.50 because the banks with the lowest efficiency scores tend to fail or be acquired and drop out of the sample. Regarding risk and opacity characteristics, the average bank has capitalization ratio *CAPITAL RATIO* of 0.101, *TOTAL LOANS / GTA* of 0.557, *COMMERCIAL RE RATIO* of 0.146, *BROKERED DEPOSITS RATIO* of 0.007, *UNUSED COMMITMENTS RATIO* of 0.075, *CASH HOLDINGS RATIO* of 0.070, *LLA / GTA* ratio of 0.009, and a *LOAN CONCENTRATION* of 0.316. Regarding size and safety net protection characteristics, the average bank has a size *LN(GTA)* of 11.454 (mean of *GTA* is \$621.583 million) and 29.7%, 60.9%, and 9.4% have OCC, FDIC, and FRS as their primary federal regulator, respectively.²⁰ As regards ownership, 72.1% of the banks are in BHCs (BHCs), 11.5% of the banks are publicly owned, and 9% of the banks are foreign-owned. For ownership structure, the average banks has *BRANCHES/GTA* of 0.030 and *LN(NUMBER STATES)* of 0.012. In terms of competition, the average bank has a

HHI DEPOSITS of 0.086 and *PERCENT METROPOLITAN* of 0.466. Finally, local economic indicators show that the average bank is exposed in the markets in which it operates to a *CHANGE COINCIDENT INDEX* of 0.206 and *HOUSE PRICE INFLATION* of 0.426.

When looking at key variables over banking versus market financial crises, statistics are mostly consistent, except that we observe more failures and higher risk during banking crises. With regard to controls, the average bank has a higher *COMMERCIAL RE RATIO*, higher *BROKERED DEPOSITS RATIO*, higher *LLA/GTA*, negative values for the *CHANGE COINCIDENT INDEX*, and lower increases in *HOUSE PRICE INFLATION* prior to banking crises, suggesting more increases in risk in the normal times leading to banking crises.

6.2. Regression analysis based on grouping financial crises together

In this section, we discuss the main empirical results based on grouping financial crises together.

6.2.1. How does pre-crisis efficiency affect banks' likelihood of failure during financial crises?

Table 2 Panel A present the bank failure regression coefficients with minimal controls. Columns (1), (3), and (5) use the *FAILED1* measure, while columns (2), (4), and (6) show results using *FAILED2*. We use logit models and include only cost efficiency in Columns (1) and (2), only profit efficiency in Columns (3) and (4), and both efficiency measures in Columns (5) and (6). Panel B has the same format, but uses the full set of control variables.

We consistently find that pre-crisis cost efficiency statistically significantly helps banks reduce their probability of failure during financial crises. Turning to economic significance, in the most complete specifications in Panel B Columns (5) and (6), we find that moving cost efficiency during normal times from 0 to 1, i.e., from the most inefficient to the most efficient, decreases the probability of bank failure during financial crises by 64% (from 0.028 to 0.010) in Column (5) for *FAILED1* and 95% (from 0.043 to 0.002) in Column (6) for *FAILED2*. These results support the *good management channel* over the *skimping channel*, consistent with the empirical dominance of Hypothesis 1a over 1b.

The results also suggest that profit efficiency generally has no statistically or economically significant effect on the likelihood of failure. When controlling for cost efficiency, the coefficient is only marginally statistically significant in one case and much smaller than the cost efficiency effect. Since profit efficiency is inclusive of both costs and revenues, and cost efficiency has a strong negative effect on the probability of failure, these results provide at least modest evidence of the *risk-taking channel* – that revenues decline during subsequent financial crises from high revenues from additional risk-taking during pre-crisis normal times. These results suggest that neither Hypothesis 2a nor 2b empirically dominate because the cost and revenue effects cancel each other out.

Turning to the controls in **Table 2** Panel B, the coefficients generally have the predicted signs. Banks with cost and profit efficiency momentum, larger size, higher capitalization, lower ratio of total loans, members of BHCs, lower ratios of commercial real estate loans, fewer brokered deposits, less unused commitments, reduced loan loss allowance ratios, publicly traded, with positive changes in coincident indices and house price inflation, and lower loan concentrations are less likely to fail during the financial crises. The other controls do not have clear sign predictions.

6.2.2. How does pre-crisis efficiency affect bank risk during financial crises?

Table 3 presents the results for our proxies of bank risk during financial crises, *LN(ZSCORE)* and *LN(σ ROA)*, following the same format as **Table 2**. Cost efficiency decreases risk during crises in all cases, and is statistically significant in all but one case. The findings

¹⁹ The four indicators are: nonfarm payroll employment, average hours worked in manufacturing, the unemployment rate, and wage and salary disbursements deflated by the Consumer Price Index.

²⁰ This last regulatory dummy is omitted from the regressions to avoid perfect collinearity.

Table 2

Do cost and profit efficiency protect banks from failing during financial crises? – Main results (All crises).

This table reports estimates from regression estimates for analyzing whether cost and profit efficiency protect banks from failure during financial crises. Panel A presents the estimates using minimal controls, while Panel B presents the results using all controls. The dependent variables are *FAILED1* and *FAILED2*. *FAILED1* is a dummy equal to 1 during a crisis if the bank failed anytime during the crisis or of the bank became insolvent (capitalization ratio is less or equal to 2%). *FAILED2* is a dummy equal to 1 during a crisis if the bank failed anytime during the crisis. All independent variables are measured as averages over the pre-crisis periods. The key explanatory variables are cost efficiency *COSTEFF* and profit efficiency *PROFITEFF*. *COST EFF MOMENTUM* is the proportion of cost efficiency increases. *PROFIT EFF MOMENTUM* is the proportion of profit efficiency increases. *LN(GTA)* is bank size calculated as the natural log of GTA. *CAPITAL RATIO* is bank capitalization, defined as the bank's total equity divided by GTA. *TOTAL LOANS / GTA* is the ratio of total loans to GTA. *BHC MEMBER* is a dummy variable that equals one if the bank was part of a BHC at any time in the pre-crisis period. *COMMERCIAL RE RATIO* is the commercial real estate loans divided by GTA. *SUPERVISOR_OCC* and *SUPERVISOR_FDIC* are dummies that equal 1 if the OCC and FDIC are the primary supervisor of the bank, respectively; both dummies are used in regressions (left out category: *SUPERVISOR_FRSS*). *FOREIGN OWNERSHIP* is a dummy equal to 1 if a bank has 50% or more foreign ownership. *BROKERED DEPOSITS RATIO* is brokered deposits divided by GTA. *UNUSED COMMITMENTS RATIO* is unused commitments divided by GTA. *CASH HOLDINGS RATIO* is cash holdings divided by GTA. *LLA / GTA* is loan loss allowance divided by GTA. *HHI DEPOSITS* is the bank-level Herfindahl-Hirschman Index (HHI) of deposit concentration for the local markets in which the bank is present. *PERCENT METROPOLITAN* is the percentage of bank deposits in metropolitan markets (MSAs and CBSAs) as a fraction of deposits in all markets in which a bank is active. *BRANCHES/GTA* is a measure of bank organizational complexity calculated as (ratio of the number of branches the bank has active over GTA) x 1000. *LN (NUMBER STATES)* is the natural log of the number of states in which bank has branches. *PUBLICLY LISTED* is a dummy equal to 1 if a bank is listed or is part of a BHC that is listed on a stock exchange. *CHANGE COINCIDENT INDEX* is the weighted average of the changes in the Philadelphia Federal Reserve's state coincident indexes with the share of the deposits of a given bank taken as weights. *HOUSE PRICE INFLATION* is the weighted average growth in a state-level house price index with the share of the deposits of a given bank taken as weights. *LOAN CONCENTRATION* is a bank's loan portfolio concentration is measured as a Herfindahl-Hirschman Index (HHI) of the following six loan categories: commercial real estate, residential real estate, construction and industrial, consumer, agriculture, and other loans. All variables are defined in Table 1. Robust *t*-statistics adjusted for bank clustering are reported in parentheses. *, **, and *** denote significance at 10%, 5%, and 1% level.

are economically significant for the more complete LN(ZSCORE) measure, but not for σ ROA. In the most complete specification in Panel B Columns (5) and (6), we find that moving cost efficiency during normal times from 0 to 1 increases LN(ZSCORE) during financial crises by 8.5% (from 3.07 to 3.33) in Column (5), which is economically significant, and produces an average reduction in σ ROA by 33% (from 0.009 to 0.006) in Column (6). The risk results again support the *good management channel* over the *skipping channel*, and the empirical dominance of Hypothesis 1a over 1b.

Profit efficiency does not have statistically significant effects on risk in the full specification in Panel B, and has a deleterious effect on risk in Panel A, as reflected by statistically lower LN(ZSCORE). Since cost efficiency during normal times is found above to reduce risk during financial crises, the profit efficiency findings suggest that high revenues during normal times are associated with increased risk during the subsequent financial crises. Thus, the data suggest that profit efficiency during normal times may partially reflect engagement in high expected return-high risk activities that have negative consequences during subsequent crises, consistent with the *risk-taking channel* and the empirical dominance of Hypothesis 2b over 2a.

Turning to the controls, most of the coefficients are in line with expectations. Banks with more efficiency momentum, larger sizes, lower loan ratios, BHC members, lower ratios of commercial real estate loans, lower ratios of brokered deposits, positive changes in economic conditions, and lower loan concentration tend to have lower risk during subsequent financial crises.

6.2.3. How does pre-crisis efficiency affect banks' profitability during financial crises?

Table 4 presents the results for the two measures of bank profitability, ROA and ROE, again following the same format. Cost efficiency consistently increases profitability during subsequent crises, while profit efficiency has little effect. The cost efficiency coefficients are all statistically significant and are economically significant for ROE as well. In Panel B Columns (5) and (6), we find that moving cost efficiency during normal times from 0 to 1 increases ROA during financial crises by 75% (from 0.004 to 0.007) in Column (5), and increases ROE during financial crises by 51% (from 0.047 to 0.071) in Column (6). Again, the results support the *good management channel* over the *skipping channel* and are consistent with empirical dominance of Hypothesis 1a over 1b.

The profit efficiency results, by contrast, show no increase in profitability during subsequent crises. The coefficients are small, and the only ones that are significant are negative. Again, since profit efficiency is inclusive of cost efficiency, the marginal effects of higher revenues during normal times presage decreases in profitability during the following financial crises, more consistent with the *risk-taking channel* than the *charter value channel* and the empirical dominance of Hypothesis 2b over 2a.

Turning to the controls, we find that banks with more efficiency momentum, greater size, BHC membership, higher ratio of unused commitments, publicly traded, having positive changes in the local market conditions where they operate as proxied by the coincident index and house price inflation, and a lower loan concentration are

Table 3

How do cost and profit efficiency during normal times impact bank risk during financial crises? (All crises).

This table reports estimates from regression estimates for analyzing how does cost and profit efficiency during normal times impact bank risk during financial crises. Panel A presents the estimates using minimal controls, while Panel B presents the results using all controls. The dependent variables are as follows: *LN(ZSCORE)* is the log of the sum of a bank's mean *ROA* (net income over *GTA*) and mean *CAPITAL RATIO* (equity capital over *GTA*) divided by σ_{ROA} (the volatility of *ROA*), where the means of the components are calculated over the crises periods. σ_{ROA} is the volatility of return on assets *ROA* over the crises periods. All independent variables are measured as averages over the pre-crisis periods. The key explanatory variables are cost efficiency *COSTEFF* and profit efficiency *PROFITEFF*. *COST EFF MOMENTUM* is the proportion of cost efficiency increases. *PROFIT EFF MOMENTUM* is the proportion of profit efficiency increases. *LN(GTA)* is bank size calculated as the natural log of *GTA*. *CAPITAL RATIO* is bank capitalization, defined as the bank's total equity divided by *GTA*. *TOTAL LOANS / GTA* is the ratio of total loans to *GTA*. *BHC MEMBER* is a dummy variable that equals one if the bank was part of a BHC at any time in the pre-crisis period. *COMMERCIAL RE RATIO* is the commercial real estate loans divided by *GTA*. *SUPERVISOR_OCC* and *SUPERVISOR_FDIC* are dummies that equal 1 if the OCC and FDIC are the primary supervisor of the bank, respectively; both dummies are used in regressions (left out category: *SUPERVISOR_FRS*). *FOREIGN OWNERSHIP* is a dummy equal to 1 if a bank has 50% or more foreign ownership. *BROKERED DEPOSITS RATIO* is brokered deposits divided by *GTA*. *UNUSED COMMITMENTS RATIO* is unused commitments divided by *GTA*. *CASH HOLDINGS RATIO* is cash holdings divided by *GTA*. *LLA / GTA* is loan loss allowance divided by *GTA*. *HHI DEPOSITS* is the bank-level Herfindahl-Hirschman Index (HHI) of deposit concentration for the local markets in which the bank is present. *PERCENT METROPOLITAN* is the percentage of bank deposits in metropolitan markets (MSAs and CBSAs) as a fraction of deposits in all markets a bank is active. *BRANCHES/GTA* is a measure of bank organizational complexity calculated as (ratio of the number of branches the bank has active over *GTA*) x 1000. *LN (NUMBER STATES)* is the natural log of the number of states in which bank has branches. *PUBLICLY LISTED* is a dummy equal to 1 if a bank is listed or is part of a BHC that is listed on a stock exchange. *CHANGE COINCIDENT INDEX* is the weighted average of the changes in the Philadelphia Federal Reserve's state coincident indexes with the share of the deposits of a given bank taken as weights. *HOUSE PRICE INFLATION* is the weighted average growth in a state-level house price index with the share of the deposits of a given bank taken as weights. *LOAN CONCENTRATION* is a bank's loan portfolio concentration is measured as a Herfindahl-Hirschman Index (HHI) of the following six loan categories: commercial real estate, residential real estate, construction and industrial, consumer, agriculture, and other loans. All variables are defined in Table 1. Robust *t*-statistics adjusted for bank clustering are reported in parentheses. *, **, and *** denote significance at 10%, 5%, and 1% level.

more likely to have strong profit performance during subsequent financial crises.

7. Robustness checks

This section presents our robustness checks. In all cases, we use only the full specifications with both cost and profit efficiency and the broad set of controls, although most of the controls are not shown for brevity.

7.1. Effects for banking crises and market crises

We examine whether results differ for the two banking crises versus the three market crises in our sample. Table 5 shows the results. They suggest that all of our effects of cost efficiency on bank performance hold consistently during banking crises, and hold in only some cases during market crises. Our non-results for profit efficiency occur in almost all cases for both types of crises.

7.2. Excluding too-big-to-fail (TBTF) banks

Another issue is that our results may be driven by the very large banks considered too-big-to-fail (TBTF), and more likely to be bailed out in the event of problems. To mitigate this concern, we rerun our main analyses while excluding these banks. There is no formal definition of TBTF, so we use two alternative definitions. First, in every period, we deem all banks with GTA of at least \$50 billion to be TBTF, consistent with the Dodd-Frank Act definition of systemically important financial institutions (SIFIs). Second, we

classify the 19 largest institutions in each period as TBTF, consistent with the Federal Reserve's determination in 2009 that the 19 largest banks were subject to stress tests. Table 6 shows results alternatively excluding these two groups. We find similar results to our main findings, suggesting that our conclusions are not driven by the TBTF banks.²¹

7.4. Controlling for cost-to-income

To ensure robustness, we also replicate our results when controlling for a simpler measure of efficiency used in the literature – *COST-TO-INCOME*, or total bank costs relative to total revenues (e.g., Beck et al., 2013). We also separately control for *COST-TO-INCOME RANK*, computed analogously to our efficiency ranks. These results are reported in Table 7 and show that these additional variables are either marginally statistically significant or insignificant, while our main results remain qualitatively unaffected.

7.5. Alternative pre-crisis period

Our main results are based on regressions that use efficiencies and control variables computed over all time periods between crises. Using the most data reduces sensitivity to the effects of outliers. As robustness checks, we rerun our regressions while measuring efficiency and control variables averaged over the four quar-

²¹ There are not enough observations to analyze the TBTF banks by themselves.

Table 4

How do cost and profit efficiency during normal times impact bank profitability during financial crises? (All crises).

This table reports estimates from regression estimates for analyzing how does cost and profit efficiency during normal times impact bank profitability during financial crises. Panel A presents the estimates using minimal controls, while Panel B presents the results using all controls. The dependent variables are as follows: ROA is the bank return on assets over the crises periods. ROE is the bank return on equity over the crises periods. All independent variables are measured as averages over the pre-crisis periods. The key explanatory variables are cost efficiency *COSTEFF* and profit efficiency *PROFITEFF*. *COST EFF MOMENTUM* is the proportion of cost efficiency increases. *PROFIT EFF MOMENTUM* is the proportion of profit efficiency increases. *LN(GTA)* is bank size calculated as the natural log of GTA. *CAPITAL RATIO* is bank capitalization, defined as the bank's total equity divided by GTA. *TOTAL LOANS / GTA* is the ratio of total loans to GTA. *BHC MEMBER* is a dummy variable that equals one if the bank was part of a BHC at any time in the pre-crisis period. *COMMERCIAL RE RATIO* is the commercial real estate loans divided by GTA. *SUPERVISOR_OCC* and *SUPERVISOR_FDIC* are dummies that equal 1 if the OCC and FDIC are the primary supervisor of the bank, respectively; both dummies are used in regressions (left out category: *SUPERVISOR_FRS*). *FOREIGN OWNERSHIP* is a dummy equal to 1 if a bank has 50% or more foreign ownership. *BROKERED DEPOSITS RATIO* is brokered deposits divided by GTA. *UNUSED COMMITMENTS RATIO* is unused commitments divided by GTA. *CASH HOLDINGS RATIO* is cash holdings divided by GTA. *LLA / GTA* is loan loss allowance divided by GTA. *HHI DEPOSITS* is the bank-level Herfindahl-Hirschman Index (HHI) of deposit concentration for the local markets in which the bank is present. *PERCENT METROPOLITAN* is the percentage of bank deposits in metropolitan markets (MSAs and CBSAs) as a fraction of deposits in all markets in which a bank is active. *BRANCHES / GTA* is a measure of bank organizational complexity calculated as (ratio of the number of branches the bank has active over GTA) x 1000. *LN (NUMBER STATES)* is the natural log of the number of states in which bank has branches. *PUBLICLY LISTED* is a dummy equal to 1 if a bank is listed or is part of a BHC that is listed on a stock exchange. *CHANGE COINCIDENT INDEX* is the weighted average of the changes in the Philadelphia Federal Reserve's state coincident indexes with the share of the deposits of a given bank taken as weights. *HOUSE PRICE INFLATION* is the weighted average growth in a state-level house price index with the share of the deposits of a given bank taken as weights. *LOAN CONCENTRATION* is a bank's loan portfolio concentration is measured as a Herfindahl-Hirschman Index (HHI) of the following six loan categories: commercial real estate, residential real estate, construction and industrial, consumer, agriculture, and other loans. All variables are defined in Table 1. Robust t-statistics adjusted for bank clustering are reported in parentheses. *, **, and *** denote significance at 10%, 5%, and 1% level.

ters before a crisis. These results are reported in Table 8 and show results similar to the main results.²²

7.6. Effects by bank size

Prior banking research has inconclusive results on the relations between bank size and efficiency. Some studies find that large banks achieve more cost and profit efficiencies than small banks (Tecles and Tabak, 2010; Manlaginit, 2011), while others find that small banks achieve more profit efficiency than large banks (e.g., Mamatzakis et al., 2008). To account for the fact that effects of efficiency may be different for small banks ($GTA \leq \$1$ billion) and large banks ($GTA > 1$ billion), we rerun our analyses for these two bank size classes.

Table 9 shows the effects of efficiency on bank performance during financial crises for small banks and large banks. Results suggest that our main findings hold for both small and large banks, but the magnitudes of the coefficients are generally higher for the large banks, although the *t*-statistics and statistical significance are generally greater for small banks, likely due to the much larger numbers of observations.²³

7.7. Non-monotonicity of the effects

In Table 10, we rerun our tests, including quadratic terms of our cost and profit efficiency measures, *COSTEFF_SQ* and *PROFITEFF_SQ*, respectively, to account for the possibility of nonlinear relations

between bank efficiency pre-crisis and performance during crises. The coefficients on the linear terms for *COSTEFF* are all statistically significant and of the same sign as in our main specification, while the coefficients on the quadratic terms *COSTEFF_SQ* have opposing signs and are also statistically significant, consistent with the existence of U- or upside-down U-shaped relations.

We calculate the inflection points of the quadratic functions of cost and profit efficiency for each performance indicator and determine the percent of observations for which the findings run in the same direction as our main results. For the cost efficiency, the inflection points are 0.739 and 0.782 for the failure models, 0.856 and 0.896 for the risk models, and 0.807 and 1.952 for the profitability models.²⁴ We also report the percent of observations for which the main relation holds. We find that for all six dependent variables, the effects of cost efficiency go in the same direction as in our main analyses for more than 90% of the observations. Thus, the data are consistent with our conclusions that higher cost efficiency results in improved bank performance during financial crises. As in our main analysis, profit efficiency during normal times has no consistent effects on bank performance during subsequent financial crises.

8. Deeper analysis of the cost efficiency findings

Our results so far suggest that cost efficiency during normal times helps banks perform better during subsequent financial crises, consistent with the *good management channel* underlying Hypothesis 1a. We next examine more carefully the extent to

²² In unreported results, we also tried using up to eight quarters, and results are also consistent.

²³ In unreported results, we redefine small and large banks based on the median of bank GTA and results are qualitatively similar.

²⁴ Inflection points are calculated as $(-\text{coefficient of the linear terms}) / (2 \times \text{coefficient of the quadratic term})$.

Table 5

Do cost and profit efficiency affect bank failure, risk, and profitability during financial crises? – Banking crises and market crises results.

This table reports estimates from regression estimates for analyzing how cost and profit efficiency affect bank failure, risk, and profitability during banking crises and market crises. The dependent variables are: *FAILED1* and *FAILED2* for bank failure, *LN(ZSCORE)* and σ ROA for bank risk, and ROA and ROE for bank profitability. All independent variables are measured as averages over the pre-crisis periods. The key explanatory variables are cost efficiency *COSTEFF* and profit efficiency *PROFITEFF*. *COST EFF MOMENTUM* is the proportion of cost efficiency increases. *PROFIT EFF MOMENTUM* is the proportion of profit efficiency increases. *LN(GTA)* is bank size calculated as the natural log of GTA. *CAPITAL RATIO* is bank capitalization, defined as the bank's total equity divided by GTA. *TOTAL LOANS / GTA* is the ratio of total loans to GTA. *BHC MEMBER* is a dummy variable that equals one if the bank was part of a BHC at any time in the pre-crisis period. *COMMERCIAL RE RATIO* is the commercial real estate loans divided by GTA. *SUPERVISOR_OCC* and *SUPERVISOR_FDIC* are dummies that equal 1 if the OCC and FDIC are the primary supervisor of the bank, respectively; both dummies are used in regressions (left out category: *SUPERVISOR_FRS*). *FOREIGN OWNERSHIP* is a dummy equal to 1 if a bank has 50% or more foreign ownership. *BROKERED DEPOSITS RATIO* is brokered deposits divided by GTA. *UNUSED COMMITMENTS RATIO* is unused commitments divided by GTA. *CASH HOLDINGS RATIO* is total bank cash holdings divided by GTA. *LLA / GTA* is loan loss allowance divided by GTA. *HHI DEPOSITS* is the bank-level Herfindahl-Hirschman Index (HHI) of deposit concentration for the local markets in which the bank is present. *PERCENT METROPOLITAN* is the percentage of bank deposits in metropolitan markets (MSAs and CBSAs) as a fraction of deposits in all markets in which a bank is active. *BRANCHES / GTA* is a measure of bank organizational complexity calculated as (ratio of the number of branches the bank has active over GTA) x 1000. *LN (NUMBER STATES)* is the natural log of the number of states in which bank has branches. *PUBLICLY LISTED* is a dummy equal to 1 if a bank is listed or is part of a BHC that is listed on a stock exchange. *CHANGE COINCIDENT INDEX* is the weighted average of the changes in the Philadelphia Federal Reserve's state coincident indexes with the share of the deposits of a given bank taken as weights. *HOUSE PRICE INFLATION* is the weighted average growth in a state-level house price index with the share of the deposits of a given bank taken as weights. *LOAN CONCENTRATION* is a bank's loan portfolio concentration is measured as a Herfindahl-Hirschman Index (HHI) of the following six loan categories: commercial real estate, residential real estate, construction and industrial, consumer, agriculture, and other loans. All variables are defined in Table 1. Robust t-statistics adjusted for bank clustering are reported in parentheses. *, **, and *** denote significance at 10%, 5%, and 1% level.

Table 6

Robustness – excluding too-big-to-fail (TBTf) institutions.

This table reports estimates from regression estimates for analyzing how does cost and profit efficiency during normal times impact bank performance (failure, risk, and profitability) during financial crises when excluding the too-big-to-fail banks defined in two different ways: GTA greater or equal to 50 Billion and top 19 banks as per GTA in each time period. The dependent variable for failure are: *FAILED1* and *FAILED2*. The dependent variables for bank risk are: bank *LN(ZSCORE)* and σ ROA. The dependent variables for bank profitability are: *ROA* and *ROE*. All independent variables are measured as averages over the pre-crisis periods. The key explanatory variables are cost efficiency *COSTEFF* and profit efficiency *PROFITEFF*. *COST EFF MOMENTUM* is the proportion of cost efficiency increases. *PROFIT EFF MOMENTUM* is the proportion of profit efficiency increases. *LN(GTA)* is bank size calculated as the natural log of GTA. *CAPITAL RATIO* is bank capitalization, defined as the bank's total equity divided by GTA. *TOTAL LOANS / GTA* is the ratio of total loans to GTA. *BHC MEMBER* is a dummy variable that equals one if the bank was part of a BHC at any time in the pre-crisis period. *COMMERCIAL RE RATIO* is the commercial real estate loans divided by GTA. *SUPERVISOR_OCC* and *SUPERVISOR_FDIC* are dummies that equal 1 if the OCC and FDIC are the primary supervisor of the bank, respectively; both dummies are used in regressions (left out category: *SUPERVISOR_FRS*). *FOREIGN OWNERSHIP* is a dummy equal to 1 if a bank has 50% or more foreign ownership. *BROKERED DEPOSITS RATIO* is brokered deposits divided by GTA. *UNUSED COMMITMENTS RATIO* is unused commitments divided by GTA. *CASH HOLDINGS RATIO* is total bank cash holdings divided by GTA. *LLA / GTA* is loan loss allowance divided by GTA. *HHI DEPOSITS* is the bank-level Herfindahl-Hirschman Index (HHI) of deposit concentration for the local markets in which the bank is present. *PERCENT METROPOLITAN* is the percentage of bank deposits in metropolitan markets (MSAs and CBSAs) as a fraction of deposits in all markets in which a bank is active. *BRANCHES / GTA* is a measure of bank organizational complexity calculated as (ratio of the number of branches the bank has active over GTA) x 1000. *LN (NUMBER STATES)* is the natural log of the number of states in which bank has branches. *PUBLICLY LISTED* is a dummy equal to 1 if a bank is listed or is part of a BHC that is listed on a stock exchange. *CHANGE COINCIDENT INDEX* is the weighted average of the changes in the Philadelphia Federal Reserve's state coincident indexes with the share of the deposits of a given bank taken as weights. *HOUSE PRICE INFLATION* is the weighted average growth in a state-level house price index with the share of the deposits of a given bank taken as weights. *LOAN CONCENTRATION* is a bank's loan portfolio concentration is measured as a Herfindahl-Hirschman Index (HHI) of the following six loan categories: commercial real estate, residential real estate, construction and industrial, consumer, agriculture, and other loans. Table 9

Do cost and profit efficiency affect bank failure, risk, and profitability during financial crises? – Bank size.

This table reports estimates from regression estimates for analyzing how does cost and profit efficiency during normal times impact bank performance (failure, risk, and profitability) during financial crises when clustering errors at the bank level. The dependent variable for failure are: *FAILED1* and *FAILED2*. The dependent variables for bank risk are: bank *LN(ZSCORE)* and σ ROA. The dependent variables for bank profitability are: ROA and ROE. All independent variables are measured as averages over the pre-crisis periods. The key explanatory variables are cost efficiency *COSTEFF* and profit efficiency *PROFITEFF*. *COST EFF MOMENTUM* is the proportion of cost efficiency increases. *PROFIT EFF MOMENTUM* is the proportion of profit efficiency increases. *LN(GTA)* is bank size calculated as the natural log of GTA. *CAPITAL RATIO* is bank capitalization, defined as the bank's total equity divided by GTA. *TOTAL LOANS / GTA* is the ratio of total loans to GTA. *BHC MEMBER* is a dummy variable that equals one if the bank was part of a BHC at any time in the pre-crisis period. *COMMERCIAL RE RATIO* is the commercial real estate loans divided by GTA. *SUPERVISOR_OCC* and *SUPERVISOR_FDIC* are dummies that equal 1 if the OCC and FDIC are the primary supervisor of the bank, respectively; both dummies are used in regressions (left out category: *SUPERVISOR_FRS*). *FOREIGN OWNERSHIP* is a dummy equal to 1 if a bank has 50% or more foreign ownership. *BROKERED DEPOSITS RATIO* is brokered deposits divided by GTA. *UNUSED COMMITMENTS RATIO* is unused commitments divided by GTA. *CASH HOLDINGS RATIO* is total bank cash holdings divided by GTA. *LLA / GTA* is loan loss allowance divided by GTA. *HHI DEPOSITS* is the bank-level Herfindahl-Hirschman Index (HHI) of deposit concentration for the local markets in which the bank is present. *PERCENT METROPOLITAN* is the percentage of bank deposits in metropolitan markets (MSAs and CBSAs) as a fraction of deposits in all markets in which a bank is active. *BRANCHES / GTA* is a measure of bank organizational complexity calculated as (ratio of the number of branches the bank has active over GTA) x 1000. *LN (NUMBER STATES)* is the natural log of the number of states in which bank has branches. *PUBLICLY LISTED* is a dummy equal to 1 if a bank is listed or is part of a BHC that is listed on a stock exchange. *CHANGE COINCIDENT INDEX* is the weighted average of the changes in the Philadelphia Federal Reserve's state coincident indexes with the share of the deposits of a given bank taken as weights. *HOUSE PRICE INFLATION* is the weighted average growth in a state-level house price index with the share of the deposits of a given bank taken as weights. *LOAN CONCENTRATION* is a bank's loan portfolio concentration is measured as a Herfindahl-Hirschman Index (HHI) of the following six loan categories: commercial real estate, residential real estate, construction and industrial, consumer, agriculture, and other loans. All variables are defined in Table 1. Robust *t*-statistics adjusted for bank clustering are reported in parentheses. *, **, and *** denote significance at 10%, 5%, and 1% level.

which this channel explains the data and whether or not the alternative *skipping channel* may find any support.

To do so, we first test whether the cost efficiency-performance relations are stronger for well managed versus poorly managed banks using regulatory enforcement actions against bank management data in the pre-crisis period to proxy for management quality following the extant research (e.g., Duchin and Sosyura, 2014; Fiordelisi et al., 2015; Delis et al., 2016). Banking regulators issue formal, publicly announced enforcement actions against bank management officials if these individuals are found to engage in unsafe, unsound, or illegal banking practices,²⁵ or other significant violations of laws, rules, or regulations. Information on regulatory enforcement actions against management is acquired via manual collection from the federal regulators OCC, FDIC, and FRS. We group banks according to whether they did not or did receive enforcement actions against management in the pre-crisis period, *Enforcement Actions against Management* = 0 or *Enforcement Actions against Management* > 0, and estimate the model for both subsamples. To the extent that the *good management channel* is in effect, it is expected that cost efficiency would have its most favorable effects for the better-managed banks that have no enforcement actions.

Regression estimates testing this are shown in Table 11, columns (1) through (12), where we show the full specifications for the performance measures for the subsamples of banks without and with enforcement actions. The effects of cost efficiency are statistically significant in all cases for the banks without enforcement actions. In contrast, they are insignificant in all cases and have the opposing signs for failure and profitability for banks with enforcement actions.

Results for the banks without enforcement actions are also economically significant. For these banks, moving cost efficiency during normal times from 0 to 1 decreases the probability of bank failure during financial crises by 64% (from 0.028 to 0.010) in Column (1) for *FAILED1* and 96% (from 0.045 to 0.002) in Column (6) for *FAILED2*. Similarly, looking at bank risk for banks without enforcement actions, we find that moving cost efficiency during normal times from 0 to 1 increases *LN(ZSCORE)* during financial crises by 8.5% (from 3.07 to 3.33) in Column (5), and reduces σROA by 22% (from 0.009 to 0.007) in Column (6). Finally, we find that moving normal-times cost efficiency from 0 to 1 for banks without actions increases *ROA* during financial crises by 75% (from 0.004 to 0.007) in Column (9), and increases *ROE* during financial crises by 51% (from 0.047 to 0.071) in Column (10). The results are strongly consistent with the *good management channel* – the effects of normal-times cost efficiency on subsequent financial crisis performance are only favorable and statistically and economically significant for the banks with no enforcement actions against management.

Table 11 columns (13) and (14) provide direct tests of the *skipping channel* by examining whether high cost efficiency during normal times is associated with more loan performance problems during subsequent financial crises. To measure loan performance problems, we use the ratio of nonperforming loans (past due at least 90 days or in nonaccrual status) to total loans, *NPL*, and the ratio of the loan and lease loss allowance to total loans, *LLA*. The evidence does not support the *skipping channel* – cost efficiency is instead associated with fewer loan performance problems.²⁶

²⁵ Unsafe or unsound practices are any actions or omissions which are contrary to generally accepted standards of prudent bank operation and, if continued, are likely to lead to abnormal risk or loss to the institution and its stakeholders.

²⁶ In unreported results, we rerun tests for small banks (*GTA* ≤ \$1 billion) and large banks (*GTA* > \$1 billion) and find that both small and large banks with higher cost efficiency in the pre-crisis period experience fewer loan performance problems during financial crises.

9. Conclusions

We test the effects of bank efficiency in normal times on bank performance during subsequent financial crises. We find that cost efficiency during normal times helps banks reduce failure probabilities, decrease risk, and enhance profitability during subsequent financial crises, while profit efficiency has limited benefits. This suggests that cost efficiency may better proxy management quality, while profit efficiency may partially reflect temporary high returns during normal times from risky investments that are reversed during subsequent financial crises. Results are robust to various checks. A deeper analysis confirms that high cost efficiency is associated with good management.

These results also yield important potential policy and research implications. Our findings suggest that bank stakeholders – policy-makers, regulators, supervisors, owners, creditors, and managers – may consider closer monitoring of banks with low cost efficiency early so as to reduce the occurrence of problems during future financial crises. In addition, bank managers may consider policies and procedures that promote cost efficiency, which may drive better bank performance during subsequent crises. With respect to research implications, our findings suggest that researchers consider relying more on cost efficiency as an indicator of bank quality than profit efficiency. The results also suggest that future research focus more on intertemporal issues in banking – what happens during normal times has important implications for subsequent financial crises.
